### Abstract

[[Joshua: Needs to be rewritten to be more general and use computers as the application not the focus]] Computers are deterministic dynamical systems [1]. Among other things, that implies that one should be able to use deterministic forecast rules to predict aspects of their behavior. That statement is sometimes—but not always—true. The memory and processor

---

<sup>‡</sup>lizb@colorado.edu

loads of some simple programs are easy to predict, for example, but those of more-complex programs like `403.gcc` are not. The goal of this paper is to determine why that is the case. We conjecture that, in practice, complexity can effectively overwhelm the predictive power of deterministic forecast models. To explore that, we build models of a number of performance traces from different programs running on different Intel-based computers. We then calculate the *permutation entropy*—a temporal entropy metric that uses ordinal analysis—of those traces and correlate those values against the prediction success.

# 1 Introduction

## BRAINSTORMING

- Complexity need not be hard to predict (can point at the simple predictions paper) [[move to introduction]]
- random walk for example is best predicted by guess what just happend[[move to introduction]]
- The kind of complexity present matters, i.e., that is whether the complexity is structured or not. [[use here and mention in intro]]
- `col_major` brings about the point nicely that some prediction strategies cannot utilize the processes internal information transfer method. That is a nonlinear internal information transfer system cannot be predicted effectively with a linear strategy. This gives a practitioner leverage on when to give up and when to keep working. [[use in this section as bridge to next section]]

Things to add to introduction

1. Different kinds of complexity exist in time series and this makes choosing prediction models difficult  

NOTE: RW and chaos are both complex. One is predictable and one is not.
2. Make an argument that Computer Performance is a great testing ground as it omits signals that completely cover the spectrum of complexity `col_major ... 403.gcc`
3. When deterministic structure even complex structure exists that structure can be utilized for prediction.
4. For noisy real-valued time series distinguishing randomness (WN,RW) complexity from structured nonlinear / chaotic /high period / high dimensional etc complexity is (until now) very hard.

for this provide predictions of `403.gcc` and `col_major` side by side and discuss "How can we tell if we did a bad job because the method is inadequate vs the signal being too complex. Lead this into is it possible to tell if there exists structure in a time series to know if we should find a better model or not. Maybe even having 4 predictions. top being ARIMA of the above signals and bottom being LMA of the above signals. Show that one improved and one did not. Is it that we used the wrong method to predict or is it that we simply can't predict the signal better than a random walk due to high levels of internal signal complexity.

5. Introduce the two main contributions of the paper which are outlined at the beginning of the results section

\*\*\*NOTES END HERE\*\*\*

\*\*\*\*SECTION START\*\*\*\*

Complicated time series are ubiquitous in modern scientific research. Every observed time series, complicated or not, exists on a spectrum of *complexity*<sup>1</sup>. On the low end of that spectrum are time series that exhibit perfect predictive structure, i.e., signals whose future value are perfectly predicted by knowledge of past values from some “ideal” model. In particular, there is an underlying process that generates and transmits information from the past to the future in a perfectly predictable fashion. Some examples of this are constant or low-period signals. On the opposite end of this spectrum are signals which are “fully complex”, i.e., the underlying generating process creates information so rapidly that no information at all is transmitted from the past to the future. Some examples, of this are white noise or random walk processes. With signals on this side of the spectrum, knowledge of the past gives absolutely no insight into the future, *regardless* of the chosen model. In the middle of this spectrum are where complicated *and* forecast-able signals exist, e.g., deterministic chaotic trajectories, high period signals with some level of noise on top. With time series in this portion of the spectrum, enough information is being transmitted from the past to the future that given the *ideal* model the future of the observed system could be forecast with high accuracy.

Unfortunately, as a corollary of the undecidability of the halting problem: there cannot exist *one* universally ideal forecasting scheme for even completely noise-free deterministic time series[?], let alone an arbitrary time series. This naturally leads to an important and hard question: given a complicated real-valued time series, is it possible to reliably quantify where on this spectrum the time series lies? That is, when little or nothing is known about the underlying system’s generating process (e.g., linear, nonlinear, deterministic, stochastic, stationary, non-stationary etc.) how can we infer from a noisy real-valued time series if the signal is too *complex* to forecast?

To answer this question and for the purposes of this paper we focus on real-valued (possibly) noisy scalar time series which appear *complicated*, i.e., they exhibit interesting behavior, for instance, not of low period, strictly monotonic, or constant. We make no assumptions about the generating process’s properties,(e.g., linear, nonlinear, deterministic, stochastic, stationary, non-stationary, etc.) and we attempt to measure empirically where on the previously mentioned spectrum of *complexity* the time series exists. We argue that *permutation entropy* [2], a method for measuring the entropy of a real-valued-finite-length noisy time series through ordinal analysis, is an effective way to explore that conjecture. For the purposes of this paper we define complexity as *permutation entropy*, which we define and explain rigorously in Section 6. To validate these claims we model the time series using a variety of forecasting models which we introduce in Section ???. We then compare the empirically estimated *complexity* with the accuracy of each forecast method. Which results in two primary findings:

1. The complexity of a noisy real-valued time series is quantifiable.
2. The way information is processed internally by a given process plays a crucial role in the success of different forecasting schema.

[[Move this up]] To explore this conjecture we require a test bed for generating a broad array of time series to analyze which covers the full spectrum of complexity. We argue that the ideal test

---

<sup>1</sup>An approx of (blah ) entropy which we make more rigorous in blah

bed for this purpose is computer performance. Computers are among the most complex engineered artifacts in current use. Modern microprocessor chips contain multiple processing units and multi-layer memories, for instance, and they use complicated hardware/software strategies to move data and threads of computation across those resources. These features—along with all the others that go into the design of these chips—make the patterns of their processor loads highly complicated. Accurate forecasts of these quantities, if one could construct them, could be used to improve computer design. Computer performance traces are, however, very complicated and range across the entire spectrum of complexity, making this an ideal test bed. Even a simple “microkernel,” like a three-line loop that repeatedly initializes a matrix in column-major order, can produce everything from periodic to *chaotic* performance traces [1], depending on the architecture running the software. Such a performance trace is shown in Figure 1. With a single system producing complicated time

Figure 1: A small snippet of the instructions per cycle(ipc) of `col_major`, a three-line C program that repeatedly initializes a matrix in column-major order, running on an Intel i7<sup>®</sup>-based machine. Even this simple program exhibits chaotic performance dynamics.

series that vary so greatly in complexity, it would be invaluable to know a priori if a trace contained enough predictive structure to forecast before time and effort was spent on trying to model and forecast it.

The computer systems community has applied a variety of prediction strategies to traces like this, most of which employ regression. An appealing alternative builds on the recently established fact that computers can be effectively modeled as deterministic nonlinear dynamical systems [1]. This result implies the existence of a deterministic forecast rule for those dynamics. In particular, one can use *delay-coordinate embedding* to reconstruct the underlying dynamics of computer performance, then use the resulting model to forecast the future values of computer performance metrics such as memory or processor loads [3]. In the case of simple microkernels like the one that produced the trace in Figure 1, this deterministic modeling and forecast strategy works very well. In more-complicated programs, however, such as numerical software or compilers, this forecast strategy—as well as the traditional methods—break down some of the time, but work fine others.

This paper is a first step in understanding when, why, and how deterministic forecast strategies fail when they are applied to deterministic systems. We focus here on the specific example of computer performance but believe the results apply to a much broader class of time series. We conjecture that the complexity of traces from these systems—which results from the inherent dimension, non-linearity, and non-stationarity of the dynamics, as well as from measurement issues like noise, aggregation, and finite data length—can make those deterministic signals *effectively* unpredictable. We argue that *permutation entropy* [2], a method for measuring the entropy of a real-valued-finite-length time series through ordinal analysis, is an effective way to explore that conjecture. We study three examples—a simple microkernel and two complex programs: one from the SPEC 2006CPU benchmark suite, and one from LAPACK—running on an Intel i7-based machine. For each program, we calculate the permutation entropy of the processor load (instructions per cycle), then compare that to the prediction accuracy attainable for that trace using a series of deterministic models.

It is worth taking a moment to consider the theoretical possibility of this task. We are not attempting to predict the state of the CPU at an arbitrary point in the future — this, at least with perfect accuracy, would be tantamount to solving the halting problem. What we are attempting is to predict aspects or functions of the running of the CPU: instructions executed per second, cache misses per 100,000 instructions, and similar statistics. Prediction of these quantities at some finite time in the future, even with perfect accuracy, does not violate the Rice-Shapiro theorem.

The rest of the paper is organized as follows. Section 4 describes the experimental setup, as well as the nonlinear modeling and forecast strategies. In Section 6, we review permutation entropy, calculate its value for a number of different computer performance traces, and compare the results to the prediction accuracy. In Section 8, we discuss these results and their implications in regard to our conjecture, and consider future areas of research.

## 2 Related Work

Attempting to model and characterize predictability is a very old problem which arguably began with Yule in 1927 when he invented AR and many attempts to quantify predictability have followed including ....

Entropy though Generating partitions works **if** you have generating partition but not if you don't

Redundancy (details in SFI forecasting), relies heavily on either estimating the generating partition which is hard to do **and** estimating the positive lyap spectrum which is hard to do for noisy systems and impossible for systems that are not deterministic.

DVS plots, gives pros and cons in (SFI prediction book)

predicting local predictive capacity (radial basis functions stuff, trying to predict error bounds on next forecast based on ensemble uncertainty) but does not aggregate tell you at what level the time series exhibits complexity only locally predictive structure, this actually gets at the interesting point that different regions of a time series may exhibit different levels of complexity which we will illustrate with **dgesdd**

Distribution of error. For many methods, if your error is not normally distributed this signals that there is still more predictive structure to that could be used by for example a larger order ARMA process. But if error is normally distributed, this suggests that you have used up all the predictive structure that **that** model can use, this doesn't quantify if predictive structure exists that isn't being used by this process. For example, nonlinear structure which is ignored by a linear predictor.

But this method is different because it uses no assumption about the underlying model, does not require generating partitions, is applicable to noisy real-valued time series.

Maybe talk about “wpe has been applied to predicting irregularities in brain wave data but no one has examined its correlation with predictive structure.” but kind of puts the cart before the horse

### 5.1.1 Reconstructing hidden dynamics

Delay-coordinate embedding allows one to reconstruct a system’s full state-space dynamics from a *single* scalar time-series measurement—provided that some conditions hold regarding that data. Specifically, if the underlying dynamics and the measurement function—the mapping from the unknown state vector  $\vec{X}$  to the scalar value  $x$  that one is measuring—are both smooth and generic, Takens [4] formally proves that the delay-coordinate map

$$F(\tau, m)(x) = ([x(t) \ x(t + \tau) \ \dots \ x(t + m\tau)])$$

from a  $d$ -dimensional smooth compact manifold  $M$  to  $Re^{2d+1}$ , where  $t$  is time, is a diffeomorphism on  $M$ —in other words, that the reconstructed dynamics and the true (hidden) dynamics have the same topology.

This is an extremely powerful result: among other things, it means that one can build a formal model of the full system dynamics without measuring (or even knowing) every one of its state variables. This is the foundation of the modeling approach that is used in this paper. The first step in the process is to estimate values for the two free parameters in the delay-coordinate map: the delay  $\tau$  and the dimension  $m$ . We follow standard procedures for this, choosing the first minimum in the average mutual information as an estimate of  $\tau$  [5] and using the false-neighbor method of [6], with a threshold of 10%, to estimate  $m$ . A plot of the data from Figure 1, embedded following this procedure, is shown in Figure 3.

The coordinates of each point on this plot are differently delayed elements of the `col_major` L2 cache miss rate time series  $y(t)$ : that is,  $y(t)$  on the first axis,  $y(t + \tau)$  on the second,  $y(t + 2\tau)$  on the third, and so on. Structure in these kinds of plots—clearly visible in Figure 3—is an indication of determinism<sup>2</sup>. That structure can also be used to build a forecast model.

---

<sup>2</sup>A deeper analysis of Figure 3—as alluded to on the previous page—supports that diagnosis, confirming the presence of a chaotic attractor in these cache-miss dynamics, with largest Lyapunov exponent  $\lambda_1 = 8000 \pm 200$  instructions, embedded in a 12-dimensional reconstruction space [1].

Figure 3: [[Joshua:Perhaps add a similar graphic of `403.gcc` to show contrast]] A 3D projection of a delay-coordinate embedding of the trace from Figure 1 with a delay ( $\tau$ ) of 100,000 instructions.

### 5.1.2 LMA: Using dynamics in forecasting

Given a nonlinear model of a deterministic dynamical system in the form of a delay-coordinate embedding like Figure 3, one can build deterministic forecast algorithms by capturing and exploiting the geometry of the embedding. Many techniques have been developed by the dynamical systems community for this purpose (e.g., [7, 8]). Perhaps the most straightforward is the “Lorenz method of analogues” (LMA), which is essentially nearest-neighbor prediction in the embedded state space [9]. Even this simple algorithm—which builds predictions by finding the nearest neighbor in the embedded space of the given point, then taking that neighbor’s path as the forecast—works quite well on the trace in Figure 1, as shown in Figure ?? . On the other hand, if we use the same approach to forecast the processor load<sup>3</sup> of the `482.sphinx3` program from the SPEC `cpu2006` benchmark suite, running on an Intel i7<sup>®</sup>-based machine, the prediction is far less accurate; see Figure ?? .

This begs the question: If these traces all come from deterministic systems—computers—then why are they not equally predictable? Our conjecture is that the sheer complexity of the dynamics of the SPEC benchmarks running on the Intel i7<sup>®</sup> machine make them effectively impossible to predict.

Figure 4: For each of these, we plot the predicted value  $p_n$  against the correct value  $c_n$ . On this type of plot a perfect prediction lies exactly on the diagonal, that is the line  $p_n = c_n$ , e.g., 4f is a near perfect prediction whereas 4c is a very poor prediction.

## 5.2 Autoregressive-integrated-moving average(ARIMA)

## 5.3 Naive: Random Walk and naïve

## 5.4 Prediction Accuracy: Mean Absolute Scaled Error (MASE)

In order to analyze correctness of each prediction we split each time series into two pieces: the first 90% referred to as the “learning” or “training” signal,  $\{X_{i,obs}\}_{i=1}^n$  and the last 10% known as the “test” or “correct” signal  $\{c_j\}_{j=n+1}^{k+n+1}$ . The learning signal is used to train an initial model (e.g., LMA or ARIMA) as described in Section 4. The test signal is used both to assess the models forecasting accuracy and for any refitting that may be necessary. In particular, we perform  $k$  1-step predictions, after each 1-step prediction<sup>4</sup> we append the training signal with the next point in the correct signal  $c_j$ , refit the model taking into account the new system measurement and perform another prediction. This is repeated  $k$  times to obtain  $\{p_j\}_{j=n+1}^{k+n+1}$ .

As a figure of merit we calculate the Mean Absolute Squared Error (MASE)[10] between the true and predicted signals:

$$MASE = \sum_{j=n+1}^{k+n+1} \frac{|c_j - p_j|}{\frac{k}{n-1} \sum_{i=2}^n |X_{i,obs} - X_{i-1,obs}|}$$

The scaling term for MASE:

$$\frac{1}{n-1} \sum_{i=2}^n |X_{i,obs} - X_{i-1,obs}|$$

is the average in-sample forecast error for a random walk prediction ( $p_i = X_{i-1,obs}$ ). This error method was introduced in [10] as a “generally applicable measurement of forecast accuracy without the problems seen in the other measurements.” The major advantage of MASE is that it allows fair comparison across methods, prediction horizons and varying signal scales. When a forecast results in a  $MASE < 1$  this means that the prediction method gave, on average, smaller errors than the 1-step errors from the in-sample random walk forecast strategy. Analogously,  $MASE > 1$  means that the prediction method did worse, on average than the 1-step errors for the in-sample random walk forecast strategy. In Table 1 we provide the distribution [[Joshua: Ryan, Is this the right word? we give mean  $\pm$  std. dev but some have very skewed right tails]] of MASEs for each of the 8 signals and 3 prediction strategies, these are averaged over 15 runs of each type (signal + method). [[and cherry pick a few examples of `403.gcc` and `col_major` to put in the text For comparison Table 1 also has the distribution of weighted permutation entropies for word lengths of  $l = 6$ .]]

## 6 Measuring Structural Complexity

### THINGS TO DO

1. rewrite for consistency in notation. For example, some parts of the paper call word length  $l$  and some call it  $n$ .

---

<sup>3</sup>Instructions per cycle, or IPC

<sup>4</sup>We would like to note that this rebuilding occurs due to a problem with ARIMA models converging to a mean prediction if too long of a prediction horizon is used, this is not a handicap of either LMA or naïve.

2. make sure it is clear and we justify that detecting and characterizing structural complexity is hard for real-valued noisy time series.
3. Quantifying structured and unstructured complexity is nontrivial in the case of real-valued noisy time series but WPE does this. [[talk about again here but justify in information theory section]]
4. justify and explain the regime split in `dgesdd`

For the purposes of this paper, one can view entropy as a measure of complexity and predictability in a time series. A high-entropy time series is almost completely unpredictable—and conversely. This can be made more rigorous: Pesin’s relation [11] states that in chaotic dynamical systems, the Shannon entropy rate is equal to the sum of the positive Lyapunov exponents,  $\lambda_i$ . The Lyapunov exponents directly quantify the rate at which nearby states of the system will diverge with time:  $|\Delta x(t)| \approx e^{\lambda t} |\Delta x(0)|$ . The faster the divergence, the more difficult prediction becomes.

Utilizing entropy as a measure of temporal complexity is by no means a new idea [12, 13]. Its effective usage requires categorical data:  $x_t \in \mathcal{S}$  for some finite or countably infinite *alphabet*  $\mathcal{S}$ , whereas data taken from real-world systems is effectively real-valued. To get around this, one must discretize the data—typically achieved by binning. Unfortunately, this is rarely a good solution to the problem, as the binning of the values introduces an additional dynamic on top of the intrinsic dynamics whose entropy is desired. The field of symbolic dynamics studies how to discretize a time series in such a way that the intrinsic behavior is not perverted, but these methods are fragile in the face of noise and require further understanding of the underlying system, which defeats the purpose of measuring the entropy in the first place.

Bandt and Pompe introduced the *permutation entropy* (PE) as a “natural complexity measure for time series” [2]. Permutation entropy employs a method of discretizing real-valued time series that follows the intrinsic behavior of the system under examination. Rather than looking at the statistics of sequences of values, as is done when computing the Shannon entropy, permutation entropy looks at the statistics of the *orderings* of sequences of values using ordinal analysis. Ordinal analysis of a time series is the process of mapping successive time-ordered elements of a time series to their value-ordered permutation of the same size. By way of example, if  $(x_1, x_2, x_3) = (9, 1, 7)$  then its *ordinal pattern*,  $\phi(x_1, x_2, x_3)$ , is 231 since  $x_2 \leq x_3 \leq x_1$ . This method has many features; among other things, it is generally robust to observational noise and requires no knowledge of the underlying mechanisms.

**Definition** (Permutation Entropy). *Given a time series  $\{x_t\}_{t=1,\dots,T}$ . Define  $\mathcal{S}_n$  as all  $n!$  permutations  $\pi$  of order  $n$ . For each  $\pi \in \mathcal{S}_n$  we determine the relative frequency of that permutation occurring in  $\{x_t\}_{t=1,\dots,T}$ :*

$$p(\pi) = \frac{|\{t | t \leq T - n, \phi(x_{t+1}, \dots, x_{t+n}) = \pi\}|}{T - n + 1}$$

Where  $|\cdot|$  is set cardinality. The permutation entropy of order  $n \geq 2$  is defined as

$$H(n) = - \sum_{\pi \in \mathcal{S}_n} p(\pi) \log_2 p(\pi)$$

Notice that  $0 \leq H(n) \leq \log_2(n!)$  [2]. With this in mind, it is common in the literature to normalize permutation entropy as follows:  $\frac{H(n)}{\log_2(n!)}$ . With this convention, “low” entropy is close to

0 and “high” entropy is close to 1. Finally, it should be noted that the permutation entropy has been shown to be identical to the Shannon entropy for many large classes of systems [14].

Here we will be utilizing a variation of the permutation entropy, the *weighted permutation entropy* (WPE) [15]. The weighted permutation entropy attempts to correct for observational noise which is larger than some trends in the data, but smaller than the larger scale features — for example, a signal that switches between two fixed points with noise about those fixed points. The weighted permutation entropy would be dominated by the switching rather than by the stochastic fluctuation. To accomplish this, the *weight* of a permutation is taken into account:

$$w(x_{t+1:t+n}) = \frac{1}{n} \sum_{x_i \in \{x_{t+1:t+n}\}} (x_i - \bar{x}_{t+1:t+n})^2$$

where  $x_{t+1:t+n}$  is a sequence of values  $x_{t+1}, \dots, x_{t+n}$ , and  $\bar{x}_{t+1:t+n}$  is the arithmetic mean of those values.

The weighted probability of a permutation is then:

$$p_w(\pi) = \frac{\sum_{t \leq T-n} w(x_{t+1:t+n}) \cdot \delta(\phi(x_{t:t+n}), \pi)}{\sum_{t \leq T-n} w(x_{t+1:t+n})}$$

where  $\delta(x, y)$  is 1 if  $x = y$  and 0 otherwise. Effectively, this weighted probability enhances permutations involved in “large” features and demotes permutations which are small in amplitude relative to the features of the time series. The weighted permutation entropy is then:

$$H_w(n) = - \sum_{\pi \in \mathcal{S}_n} p_w(\pi) \log_2 p_w(\pi),$$

which can also be normalized by dividing by  $\log_2(n!)$ , and will be in all the results of this paper.

In practice, calculating permutation entropy and weighted permutation entropy involves choosing a good value for the word length  $n$ . The primary consideration is that the value be large enough that forbidden ordinals are discovered, yet small enough that reasonable statistics over the ordinals are gathered: e.g.:

$$n = \operatorname{argmax}_{\ell} \{T \gtrsim 100\ell!\},$$

assuming an average of 100 counts per ordinal is sufficient. In the literature,  $3 \leq n \leq 6$  is a standard choice — generally without any formal justification. In theory, the permutation entropy should reach an asymptote with increasing  $n$ , but that requires an arbitrarily long time series. In practice, what one should do is calculate the *persistent* permutation entropy by increasing  $n$  until the result converges, but data length issues can intrude before that convergence is reached.

The weighted permutation entropy for the SVD program is given in Fig. 5. To generate this image a window of 5,000 values slid over the time series. Within each of those windows, the statistics over words of length 4 are computed and the WPE is calculated. The gray bands denote regions where the 5,000 value window overlapped visually-distinct regimes. It can be seen that the behaviors of the weighted permutation entropy vary between regimes. [[I think here it would be good to add a paragraph explaining the windowed WPE was used for regime choices on SVD...emphasizing that over a time series permutation entropy fluctuates illustrating within a single time series different levels of complexity and predictability exist. Maybe point at some of the predicting predictability papers.]]

Liz commented this image out temporarily so that her mac doesn't hang when she scrolls past p12

Figure 5: [Joshua: I think adding the colored SVD trace to this would be good or putting it above this figure but need to figure how to line them up properly. Also we need to label that the numbers on the bottom of WPE are regimes not instructions...]The weighted permutation entropy of one run of SVD. The gray bands are regions where the window overlaps regimes. The window size used is  $5,000 \times 100,000$  instructions and the word length is 4.[Joshua:why is  $l = 4$  and not 5,6 like the rest of the paper?]]For reference the instructions per cycle of `dgesdd` are plotted as a ghost behind this plot. Each color on the ghosted time series corresponds to the different regimes as selected by rapid shifts in WPE. From left to right each change in color represents a change in regime for 6 regimes in total.

## 7 Predictability, Complexity, and Permutation Entropy

In this section, we offer an empirical validation of the two key conjectures introduced in Section 1, namely:

1. that the weighted permutation entropy (WPE) of a noisy real-valued time series is correlated with prediction accuracy—i.e., that the predictable structure in a time-series data set can be quantified by its WPE.
2. that the way information is processed internally by a system is correlated with the effectiveness of a given predictor on time-series data from that system

The experiments below involve the three different prediction methods described in Section 4—naïve, ARIMA, and LMA—applied to time-series data from eight different systems: `col_major`, `403.gcc`, and the six different regimes of the `dgesdd` signal in Figure 5. The objective of these experiments was to explore how prediction accuracy is related to WPE, and how that relationship depends on the generating process and the prediction method. Working from the first 90% of each signal, we generated a prediction of the last 10% of that signal using each of the methods, as described in Section 5.4, then calculated the MASE value of those predictions. We also calculated the WPE of each time series, as described in Section 6, using a wordlength of six. In order to assess the run-to-run variability of these results, we repeated all of these calculations on 15 separate trials: i.e., 15 different runs of each program. Figure 6 shows the *best* of these 45 predictions for each system: i.e., the lowest error over all 15 trials and all three methods for each program. The WPE is plotted against the corresponding MASE value in order to bring out the correlation between these two quantities.

The best-case prediction error for each of these eight systems is roughly proportional to the weighted permutation entropy, which is consistent with our first conjecture. The dashed line in the figure, a linear least-squares fit to these best-case errors—with the exception of `dgesdd5`, for reasons described below—captures this rough proportionality. This is not a formal result. The three methods used here were chosen to span the space of standard prediction strategies, but they do not, of course, cover that space exhaustively. Our goal here is an empirical assessment of predictability and complexity, not formal results about a “best” predictor for a given time series. There may be other methods that produce lower MASE values than those in Figure 6, but the sparseness of the points in the upper-left and lower-right quadrants of this plot strongly suggests that the underlying predictability of a time series is inversely correlated with its WPE. The rest of this section describes

Figure 6: Weighted permutation entropy vs. mean absolute scaled error (MASE) of the best prediction of each system. The dashed line is a least-squares linear fit of all the points except `dgesdd1`, which we have excluded for reasons explained in the text. [[Ryan, is that correct?]]

our results in more detail, including the measures taken to assure meaningful comparisons across methods, trials, and programs, and elaborates on the meaning of the dashed line in the figure.

Figure 7 shows WPE vs. MASE plots for all 360 experiments. There are 15 points in each cluster, one for each trial<sup>5</sup>. (The points in Figure 6 are the leftmost points in any of the three clusters for the corresponding system.) Most of the clusters are quite tight. Some are flat and wide because the WPE values of each run of any particular program tend to have little variance; for most traces, the LMA and ARIMA variance is low as well, resulting in small, tight clusters. The *spatial distribution* of the clusters is quite different in the three plots: LMA is tight around the dashed line, whereas naive and ARIMA are [[need to fill in words here when get the third image]]. This is a geometric validation of the second conjecture in this paper, as described in the following paragraphs.

Though `col_major` is a very simple program, its dynamics are actually quite complicated, as discussed in Section 1. Recall from the right-hand column of Figure 4 that the naive and ARIMA prediction methods perform poorly on this signal (MASE values  $0.57 \pm 0.001$  and  $0.59 \pm 0.21$ , respectively). That is, the errors produced by these methods are a little over half as large as the errors produced by the random-walk method, which simply uses the current value as the prediction. However, the WPE value for the `col_major` trials is  $0.51 \pm 0.003$ : i.e., right in the middle of the complexity spectrum described in Section 1, implying that roughly half of the signal is predictive structure. This disparity—WPE values that suggest a high rate of forward information transfer in the signal, but predictions with low MASE scores—manifests geometrically in the top two images in Figure 7, where the `col_major` clusters are far to the right of the dashed line. This is important; it says that the methods aren’t leveraging that information very well. This is not surprising, really. The dynamics of `col_major` may be complicated, but they are not unstructured. This signal is nonlinear, deterministic, and chaotic. Indeed, if you use a prediction technique that uses a nonlinear model (LMA) you get a MASE of  $0.05 \pm 0.001$ —i.e., 20 times more accurate than a random-walk

<sup>5</sup>A trial involves collecting a time series from the corresponding system, predicting the last 10% of that time series, and calculating the MASE score.

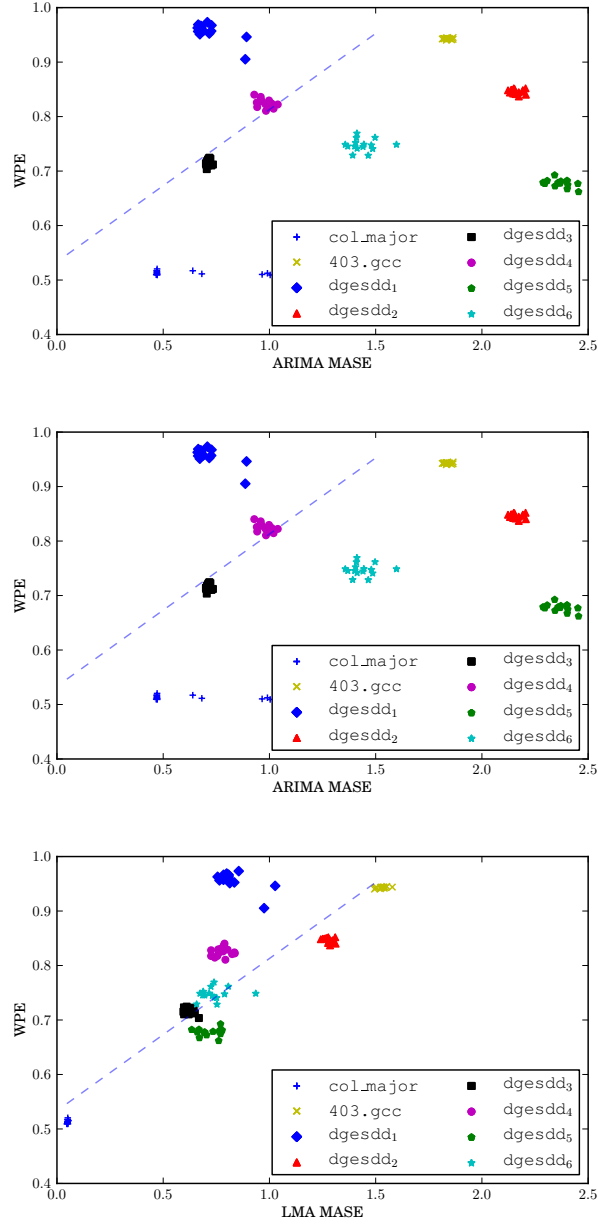

Figure 7: WPE vs. MASE for all trials, methods, and systems. `dgesdd1`, `dgesdd3`, and `dgesdd5` are omitted from the top plot for scale reasons; their MASE scores are  $2.6763 \pm 4.3282$ ,  $31.3857 \pm 0.2820$ , and  $20.8703 \pm 0.1915$  respectively. **Replace the top plot with a plot of the naive results—but running from 0 to 3.1 on the horizontal axis and excluding SVD 1, 3, and 5.** The dashed line is the same as in the previous figure [[Ryan, is this correct?]]. Numerical values, including means and standard deviations of the errors, can be found in Table 1 in the appendix.

forecast. Note the position of the `col_major` cluster in the bottom image in Figure 7: much closer to the dashed line. From a practitioner’s standpoint, what this means is that being below that line tells you that there really IS usable structure in the time series, that you could do better, and that you should use a better method. Note, too, that the `col_major` points are clustered in LMA but spread out horizontally in ARIMA, far to the right of the dashed line (i.e., much worse than the other methods). We need to come up with a hypothesis about this spread and skew, even if it’s totally tentative.

The WPE of `dgesdd5` ( $0.677 \pm 0.006$ ) is higher than that of `col_major`. This indicates that the rate of forward information transfer of the underlying process is lower, but that time-series data from this system still contain a significant amount of structure that can, in theory, be leveraged to predict the future course of the time series. However, the effectiveness of any prediction strategy will depend on how well it leverages the available information. This issue becomes apparent in the case of `dgesdd5`, as is clear from the positions of the corresponding clusters in Figure 7. The naive and ARIMA prediction strategies in the top two plots produce MASE scores of  $2.3700 \pm 0.0505$  and  $20.8703 \pm 0.1915$ , respectively: that is, 2.37 and 20.87 times worse than a simple random walk forecast of the same signals. [[This is big because the amount of variance in this signal makes it a bad idea to just guess the mean. The same thing is true of `dgesdd3`.]] [[Joshua: can you say that better—in a way that is true of both of these, and distinguishes them from all of the signals that have lower values?]] Again, the positions of the ARIMA and LMA clusters—significantly below and to the right of the dashed line—should suggest to a practitioner that there is more structure in this signal than the method is able to leverage, so s/he can do better and should try a different prediction method. In this case, the LMA method produces a MASE score of  $0.7177 \pm 0.0483$  and a cluster of results on the WPE-MASE plot that is much closer to the dashed line. This validates our second conjecture: the naive and ARIMA prediction methods, which use constant and linear models, respectively, cannot capture or reproduce the way in which the `dgesdd5` system processes information, but the nonlinear LMA method can.

The WPE of `403.gcc` is much higher:  $0.94 \pm 0.001$ . This system transmits very little information forward in time and provides almost no structure for prediction methods to work with. What we see: naive does the best, then LMA, then ARIMA. Hypothesis: that that 5% of the structure is nonlinear, so LMA can use it better than ARIMA can. Naive does better than LMA because it’s filtering out the noise.

`dgesdd1` behaves very differently than the other seven systems in this study: though its WPE is very high ( $0.95 \pm 0.02$ ), two of the three prediction methods (LMA and ARIMA) do quite well:  $0.82 \pm 0.08$  and  $0.7141 \pm 0.07$  MASE scores, respectively. Accordingly, the clusters of `dgesdd1` points in the bottom two images in Figure 7 are well above the trend followed by the other seven clusters. Also, the MASE scores of the predictions produced by the naive method are highly inconsistent:  $2.67 \pm 4.33$ . These effects, we believe, are artifacts of the way MASE is calculated. Recall that MASE scores are scaled relative to a random walk forecast, which uses the current value as the prediction. This strategy works very badly on signals with frequent, large, rapid transitions. Consider a signal that oscillates from one end of its range to the other at every step. A signal like this will have a low WPE, much like `col_major`. However, a random-walk forecast of this signal will be 180 degrees out of phase with the true continuation. Since random-walk error appears in the denominator of the MASE score, this effect can shift points leftwards on a WPE vs. MASE plot, and that is exactly why the `dgesdd1` clusters for ARIMA and LMA are above the dashed line in Figure 7. The `dgesdd1` time series, which is shown in Figure 8, is not quite to the level of the worst-case signal described above, but it poses a serious challenge to random-walk prediction. It is dominated by

Figure 8: A small portion of the `dgesdd1` time series

a white-noise regime (between 1.86 and 1.88 on the vertical scale in the Figure), punctuated by short excursions above 1.9. In the former regime, which makes up more than 80% of the signal, there are frequent dips to 1.82 and occasional larger dips below 1.8. These single-point dips are the bane of random walk forecasting. In this particular case, roughly 40% of the forecasted points are off by the width of the associated dip, which skews the associated MASE scores. Signals like this are also problematic for the naive prediction strategy, since the outliers have significant pull on the mean, which compounds the effect of the skew in the scaling factor and creates a large spread in the `dgesdd1` MASE values. For all of these reasons, we view `dgesdd1` as an outlier and thus exclude it from the fit calculation of the dashed line in Figure 6.

Comparing Figures ?? and ?? also elucidates another key finding: usable and quantifiable predictive structure can be present in a time series without a prediction scheme being able to utilize it. In particular, information may be transferred from past to future through the present but because of the mechanism the underlying process uses to process that information (e.g., linear or nonlinear) certain prediction strategies may be blind to or not be able to efficiently utilize this information. For example, consider `col_major`, programs like this have been shown to exhibit deterministic chaos [1]. If this were the case with `col_major`, an out-of-the-box linear method like ARIMA would simply be ill-equipped to model and utilize the kind of structure present, as is evident in Figure ??. In contrast, a nonlinear predictor like LMA which is built to handle deterministic chaos, can interpret and utilize this type of structure just fine. We believe that many of the shifts in forecast accuracy for low-to-moderate WPE programs between ARIMA and LMA is precisely happening for this reason: Just because there is forward information transfer, does not mean that an arbitrary predictor can interpret or utilize it, but luckily WPE can tell us when this structure is present as shown in Figure ??.

The big picture: Furthermore, since LMA can predict nonlinear behavior while ARIMA cannot, we see that the clusters in Figure ?? are mostly further to the right than those in Figure ??.

## 8 Conclusions & Future Work

1. This need to be rewritten to conclude and address this paper...

Moved the following two paragraphs here from the results section, since they're more general. But there's a lot of repeated material that will obviously need to get compressed and streamlined.

These results support that time series with low to moderate complexity ( $0 \leq WPE \leq 0.85$ ) can be predicted more efficiently than a naïve random walk *and* that complexity can be qualitatively measured for a real-valued noisy time series using WPE. This will allow practitioners to stop spinning their wheels in the case of signals who are simply better predicted with a simple strategy like random walk. The analysis of these results illuminates an interesting point: The way structure, information and complexity are processed by a generating process plays a crucial role in the success of a given prediction scheme.

As we discussed in Section 6 distinguishing structured from unstructured complexity in the case of real-valued time series is non trivial, i.e., distinguishing when a complex signal omits predictable structure and when the signal is effectively random is not a trivial task. As described in Section 1, for a practitioner this can be frustrating because it can be nearly impossible to find the source of faulty predictions: Is it simply that we need to use a more ideal (possibly more advanced) predictor or is it the case that the time series is simply so complex that using a simple (yet inconsistent) forecast strategy such as random walk is the best we can do. Fortunately, weighted permutation entropy (WPE) allows us to make this distinction for noisy real-valued time series.

Needs to be more stuff in the WPE section for this to tie back to as well as in the new related work section. [[Joshua, can you elaborate on this so that Ryan can fill this in?]]

The results presented here suggest that permutation entropy—a ordinal calculation of forward information transfer in a time series—is an effective metric for predictability of computer performance traces. Experimentally, traces with a persistent PE  $\gtrsim 0.97$  have a natural level of complexity that may overshadow the inherent determinism in the system dynamics, whereas traces with PE  $\lesssim 0.7$  seem to be highly predictable (viz., at least an order of magnitude improvement in nRM-SPE). Further, the persistent WPE values of 0.5– 0.6 for the `col_major` trace are consistent with dynamical chaos, further corroborating the results of [1].

If information is the limit, then gathering and using more information is an obvious next step. There is an equally obvious tension here between data length and prediction speed: a forecast that requires half a second to compute is not useful for the purposes of real-time control of a computer system with a MHz clock rate. Another alternative is to sample several system variables simultaneously and build multivariate delay-coordinate embeddings. Existing approaches to that are computationally prohibitive [16]. We are working on alternative methods that sidestep that complexity.
